Abstract

Aim: The aim of the paper was to estimate by immunohistochemistry the state of the rat cerebellum cortex synapses and of gamma-aminobutyric acid (GABA)-ergic neurons in cholestasis. Experimental rats were anesthetized with ethyl ether and the common bile duct was ligated 3–5 mm below the confluence of the lobar ducts. Animals of the control group underwent sham operation. On the 2nd, 5th, 10th, 20th, 45th, and 90th day the animals of the control and cholestasis groups were decapitated and the samples of their cerebellum cortex were prepared for immunohistochemistry to examine the synaptophysin (Syn) and glutamate decarboxylase (GAD) expression.

Results: On the 5th day after the ligation of the common bile duct in the molecular layer of the cerebellar cortex the expression of Syn increased by 16%, and on the 10th day by 38%, as compared to the controls. In subsequent time intervals of the study it did not differ from that of the controls. On the 2nd day after the ligation of the common bile duct the expression of GAD in the cytoplasm of Purkinje cell bodies decreased by 10%. On the 5th day of cholestasis the expression of GAD in the cytoplasm of the survived Purkinje cells increased by 28%, on the 10th day by 41%, and within 20 days it increased by 61%. On the 5th day in the baskets around PC bodies the GAD-immunoreactivity increased by 11%, on the 10th day by 39% and on the 20th day by 33%, as compared to the controls. However, on the 45th and 90th day the immunohistochemical differences were not defined, as compared to the controls.

Conclusion: Cholestasis in rats induces a compensatory increase in synaptophysin and glutamate decarboxylase expression in the cerebellum cortex.

Introduction

Cholestasis is a state when the bile cannot flow from the liver to the duodenum and accumulates in the small bile ducts. Its pressure increases dramatically and bile components are passing into the blood. Bile is a complex fluid containing bile acids, cholesterol, phospholipids, bilirubin, and proteins; it is essential for the lipids digestion in the intestine. The most important biochemical markers of cholestasis are increased levels of bilirubin, cholesterol and bile salts in blood plasma, as well as an increased activity of liver enzymes-alkaline phosphatase, gamma-glutamyl transferase, and 5' nucleotidase [1,2].

In cholestasis, primarily hydrophobic bile acids and unconjugated bilirubin increasing in blood induce significant toxic effects on the brain. One of the causes of cholestasis-induced brain damage can be hypoxia due to the disturbances of blood circulation [3]. In cholestasis, the toxic bile acids disturb the permeability and structure of blood-brain barrier [4]. Unconjugated bilirubin in the brain impairs energy metabolism and induces apoptosis, cell-membrane defects, which causes enzyme leakage and hampers transport of neurotransmitters [4]. Bilirubin also interferes with DNA and protein synthesis; it interacts directly with cell membrane phospholipids and alters intracellular pH as well. The excess of bilirubin induces excitotoxicity via glutamate NMDA receptors and caspase-dependent pathways [5]. In addition, cholestasis induces fat malabsorption related to the decrease in bile acids in the intestine and the absorption of lipids and lipids-soluble vitamins (A, D, E, and K). Vitamin E deficiency is associated with a progressive neuromuscular syndrome that can cause cerebellar ataxia [6].

The cerebellum is not only the center of balance and coordination of movements, but also participates in the regulation of many visceral

functions and higher mental processes. In our previous study we found that cholestasis damaged the neurons of the cerebellum [7], and induced in particular the loss of Purkinje cells and granule neurons [7,8]. Bilirubin toxicity of the cerebellar granule cells neurons is mediated by the activation of p38 MAP kinase [9], which induces a wide variety of cellular activity in response to extracellular stimuli [10]. In our previous studies we reported on the structural and metabolic disturbances in cerebellar Purkinje cells in rats with cholestasis [8]. But the data on the state of synapses and gamma-aminobutyric acid GABAergic structures in the cerebellum in cholestasis are still lacking.

The aim of the present paper was to assess the state of the rat cerebellum cortex synapses (by the detection of synaptic vesicles marker synaptophysin, Syn) and of gamma-aminobutyric acid (GABA)-ergic neurons (using GABA synthesis enzyme glutamate decarboxylase, GAD) by immunohistochemistry.

Community Council Directive (86/609/EEC) for care and use of laboratory animals. This study was approved by the Biomedical Ethics Committee of the Grodno State Medical University. Rats were housed in vivarium with free access to standard laboratory food and kept under controlled environmental conditions. Experimental rats were anesthetized with ethyl ether and the common bile duct was ligated 3-5 mm below the confluence of the lobar ducts by applying two ligatures followed by cross-section between them. Animals of the control group underwent sham operation. On the 2nd, 5th, 10th, 20th, 45th, and 90th day the animals of the control and cholestasis groups were decapitated, the samples of their cerebellum were collected and fixed in zinc-ethanol-formalin at 4°C (overnight) and then embedded in paraffin. To obtain comparable results the cerebellum samples were treated in identical conditions.

Immunohistochemistry

Paraffin (7 µm) sections were cut with Leica RM2125 (RTS microtome Germany). Immunohistochemical detection of Syn was done using a rabbit polyclonal primary antibody, Synaptophysin Antibody (PA5-27286, Thermo Scientific, USA), diluted 1:400 at 4°C, exposure for 20 h, in a moist chamber. Binding of primary antibodies was detected using Thermo Scientific Super Picture™ Polymer Detection Kit. Glutamate decarboxylase (GAD) was detected with mouse monoclonal primary antibodies against GAD 67, ab. 26116 (Abcam, UK), diluted 1:2000 at 4°C, exposure for 20 h, in a moist chamber. Binding of primary antibodies was detected using Expose Mouse and Rabbit Specific HRP/DAB Detection IHC Kit ab. 80436 (Abcam, UK).

For the standardization of the study in all samples the lateral zone of the posterior lobe of the cerebellar hemispheres was examined. The cerebellum cortex of this region bilaterally connected with sensorimotor brain cortex which allows to plan and coordinate the rapid movements of the body following one after each other. The levels of Syn and GAD expression in cerebellum cortex structures were determined. The histochemical preparations were examined, microphotographed and studied morphometrically using an Axioscop 2 plus microscope (Zeiss, Germany) with a Leica DFC 320 digital video camera (Leica, Germany) and image analysis program ImageWarp (Bitflow, USA).

Statistics

Mean values obtained in animals of each experimental group were analyzed by nonparametric statistics (because of the small number of animals in the groups) in Statistica 10.0 for Windows (StatSoft, USA). The descriptive statistics for each parameter included determination of the median (Me) and interquartile range (IQR). Differences between values in the control and experimental groups were regarded as significant at $p < 0.05$ using the Mann-Whitney U-test.

Results

In control animals, the expression of synaptophysin was detected in numerous presynaptic endings on the Purkinje cells dendrites in the molecular layer of the cerebellum, as well as in axosomatic synapses and baskets around Purkinje cells bodies. Syn expression was especially high in the granular layer glomeruli of the cerebellum (Figure 1 B, C). The intensity of synaptophysin expression in control animals did not change significantly at different time periods after sham operation (Table 1).

On the 2nd day after the ligation of the common bile duct in the molecular layer of the cerebellar cortex the expression of synaptophysin did not differ, on the 5th day it increased by 16%, and on the 10th day by

38%, as compared to the controls. At subsequent time intervals of the study it did not differ from that of the controls (Figure 1 B, C; Table 1).

The expression of glutamate decarboxylase (GAD67) in the Purkinje cells cytoplasm was detected (both in the bodies and dendrites) as well as in baskets around the Purkinje cell bodies. In the molecular layer GAD-immunopositive stellate and basket cells were also visible, forming numerous axosomatic and axodendritic synapses on Purkinje cells (Figure 2 A, C). In the granular layer GAD-immunopositive neurons as well as terminals on the periphery of the cerebellar glomeruli were detected (Figure 2 A, B).

On the 2nd day after the ligation of the common bile duct in the cytoplasm of Purkinje cell bodies the expression of GAD decreased by 10% (Table 2). On the 5th day of cholestasis the expression of GAD in the cytoplasm of the remaining Purkinje cells increased by 28%. The baskets around perikaryon became more visible, extended, elongated in the direction of the granular layer, and showed darker staining due to the increase in GAD-immunoreactivity by 11%. On the 10th day of cholestasis the expression of GAD in the cytoplasm of the survived Purkinje cells increased by 41% and in their baskets on 39%, respectively, as compared to the controls (Figure 2 B, Table 2). Cholestasis within 20 days led to the increase in the expression of GAD in the cytoplasm of the survived Purkinje cells by 61% and to the increase in their baskets by 33%, as compared to the controls (Figure 2 D, Table 2). However, on the 45th and 90th day after the ligation of the common bile duct the immunohistochemical differences were not defined, as compared to the controls (Table 2).

Discussion

In the present study, the ligation of the common bile duct in rats induces a temporary increase (on the 5th and 10th day) in the expression of synaptophysin in the cerebellum cortex molecular layer. The majority of synapses are formed by terminals of the granular cell axons (parallel fibers) on the Purkinje cell dendrites. Syn, an integral membrane protein of synaptic vesicles, is found in all nerve terminals and is involved in the synaptic transmission [11,12] playing an important regulatory part in synapse formation [13]. The temporary increase in synaptophysin in the cerebellum molecular layer can reflect the increased synaptogenesis, the number of synaptic vesicles in synapses and is a compensatory reaction. Cholestasis which induced the death of granular and Purkinje cells [8], structural and metabolic disturbances in cerebellar Purkinje cells appeared on the 5th day after the ligation of bile duct. It reached a maximum on the 10-20th days and decreased on the 45-90th days. In our present study on the 20-90th days after the ligation of the bile duct the expression of synaptophysin in the molecular layer of the cerebellar cortex did not differ from that of the controls. The recovery can be explained by the growing of new collateral bile ducts.

The increase in the expression of GAD in survived GABA-ergic Purkinje cells on the 5-20th days of cholestasis indicates their activation. The increase in the expression of GAD in baskets around their bodies indicates activation of GABA-ergic basket cells which can compensatory inhibits hyperexciting Purkinje cells, probably for support the functions of cerebellum.

In conclusion, cholestasis in rats induces an increase in synaptophysin and glutamate decarboxylase expression in the cerebellum cortex necessary for support the functions of cerebellum.
